Abstract

Rice stripe disease is an economically important disease of rice caused by the <i>Rice</i>
stripe virus (RSV), which is transferred by the small brown planthopper (SBPH). The
recent rapid increase in damage to rice crops throughout Japan caused by this disease
makes it imperative to develop control methods as soon as possible. To obtain basic
data for developing such methods, we studied how the disease causes damage and
spreads within paddy fields. Our investigations revealed that diseased plants first appear
in mid-June to early July, after which the disease spreads from affected plants to
adjacent plants. This suggests that SBPH carrying RSV enter paddy fields, where they
infect plants as they move about and lay eggs. Subsequently, hatched viruliferous
nymphs infect surrounding plants, thereby spreading the disease. Our analysis of the
damage caused by rice stripe disease showed that the earlier the onset of disease, the
more extensive the damage caused, and that the disease reduces yield by reducing the
number of healthy panicles. This suggests that to reduce damage caused by this disease,
it is necessary to ensure the growth of a sufficient number of healthy panicles by
controlling the vector insect during the crop's early growth period. To be most effective
pest control efforts should be timed to target either the first-generation adults that
colonize the paddy fields or the second-generation nymphs and adults that cause the
rapid increase in the number of diseased plants within a field.

1. Introduction

42	Rice stripe disease is one of the most serious viral diseases affecting rice (Oryza sativa
43	L.) crops in Japan, South Korea, and China. The disease is caused by the <i>rice stripe</i>
44	virus (RSV, Toriyama 1983), in the genus Tenuivirus (Shirako et al. 2011), which is
45	persistently transmitted by the small brown planthopper (SBPH, Laodelphax striatellus
46	(Fallén)) and is passed to the next generation by transovarial transmission (Hibino 1996;
47	Toriyama 1983). In Japan, RSV caused widespread damage from the 1960s to the
48	1980s, but was brought under control from the late 1980s through control of the vector
49	insect, increased use of RSV-resistant rice cultivars, and other measures (Hibino 1996).
50	However, in recent years, rice stripe disease has returned with a vengeance in the Kanto
51	region (the east-central area of Japan's main island), the Kinki region (the west-central
52	area of Japan's main island), and the Kyushu region (southwestern Japan) (Shiba et al.
53	2016; Yoshida et al. 2014). Serious outbreaks have also been reported in China and
54	South Korea (Jonson et al. 2009; Wang et al. 2008). It is not yet known why this disease
55	has re-emerged in East Asia, but suspected causes include the development of pesticide
56	resistance by SBPH (Sanada-Morimura et al. 2011), climate change (Yamamura and
57	Yokozawa 2002), mass immigration of SBPH from overseas (Otuka et al. 2010, 2012),
58	and changes in the cropping systems and environments surrounding production areas.
59	Susceptibility to RSV in rice varies widely with growth stage (Adachi and Yamada
60	1968, Hibino 1996, Wang et al. 2008). Rice in the early vegetative phase (from planting

to the early tillering stage) is highly susceptible to RSV. Leaves of tillers infected during this period develop a mosaic of light yellow or yellow-green lesions along their veins, and new leaves curl and droop instead of fanning out. The majority of tillers that show these symptoms wilt without heading. In the late vegetative phase (the late tillering stage), susceptibility to RSV declines, and wilting due to infection does not occur. However, infected tillers cannot head normally; instead, they produce deformed panicles. Plants in the reproductive phase following panicle initiation are less susceptible to infection, and even if they are infected, symptoms are not severe. The typical SBPH life cycle in areas of Japan prone to rice stripe disease is described by Shiba et al. (2016). Nymphs overwinter in patches of grass, and adults of the overwintering generation emerge in spring and move to adjacent wheat fields to propagate. Adults of the next generation (first generation) colonize paddy fields after rice seedlings have been planted. After three or four generations in the paddy fields, adults move to nearby grassy areas during the harvest season to lay eggs, and the next generation overwinters as nymphs. Because wheat is an ideal SBPH food source, SBPH numbers are liable to increase in areas where wheat is grown, and rice stripe disease tends to occur more frequently in these areas. Research on the epidemiology and control of rice stripe disease in Japan was

carried out intensively from the 1960s to the 1980s, but since then, factors that affect

rice stripe disease epidemiology such as the cultivar, cropping system, and surrounding

environment have changed substantially, rendering much of the knowledge gained in that period inapplicable. With rice stripe disease once more becoming pervasive in Japan, we launched a comprehensive research project to develop control techniques aimed at early containment of outbreaks. We have previously reported that measurements of the effective cumulative temperature can be used to accurately predict the appearance of SBPH in paddy fields (Hirae and Shiba 2016), and that the elimination of rice rations and of grass near paddies after harvest is critical to suppressing the disease (Shiba et al. 2016). Here, we report on the mechanism by which rice stripe disease causes damage to infected rice plants, and how the disease spreads through paddy fields. This is essential information to developing effective control techniques against the current outbreak of rice stripe disease.

2. Materials and Methods

2.1 Test plots

From 2012 to 2014, we conducted experiments in Nikinari, a district of Chikusei City, Ibaraki Prefecture, in Japan's Kanto region (36°17′N, 139°58′E), where rice stripe disease occurs every year. We planted seedlings of 'Koshihikari' (which is susceptible to RSV), Japan's most widely grown cultivar of rice, in two paddy fields in each year. In 2012, Fields A and B each covered approximately 3000 m² and were 65 m apart at

their closest points. In 2013, Fields C and D each covered approximately 7000 m² and were 60 m apart at their closest points. In 2014, Fields E and F each covered approximately 3000 m² and were 100 m apart at their closest points. The seedlings were planted 24 cm apart in rows 30 cm apart. Each field was planted in mid-May (15 May 2012, 17 May 2013, 14 May 2014) and harvested in early to mid-September (12 September 2012, 18 September 2013, 9 September 2014). No pesticides were applied during cultivation in each of the test plots. In 2012, we established rectangular plots of 30 rows with 73 plants per row in each field, and also selected individual plants within each plot for detailed observation. Every fifth plant in every third row was designated as a fixed-point-survey plant, for a total of 15 such plants per row in 10 rows. Two of those plants in Field A failed to survive. Thus, the fixed-point-survey for Field A included only 148 plants, compared with 150 in Field B. In the same manner, we established rectangular plots of 30 rows with 50 plants per row in each field and designated 99 or 100 fixed-point-survey plants within each plot in 2013 and 2014. In the experimental area, first-generation SBPH adults colonized the survey fields in mid-June, second-generation nymphs emerged in the paddy fields from late June to early July, and third-generation nymphs emerged from late July to early August according to estimates based on the measurements of the effective cumulative temperature obtained from JPP-NET (Japan Plant Protection Agency, Tokyo, Japan).

Rates of virus-infected first-generation adults of SBPH collected in rice paddies were

2.2 Disease surveys

In 2012, we investigated all plants in the survey plot in Field A to detect the presence of diseased plants on 11 July (the panicle initiation stage), on 8 and 9 August (the flowering stage), and on 4 and 5 September (immediately before harvest). In addition, on the fixed-point-survey plants, we counted the numbers of total, diseased, and healthy panicles during the survey in early August. In Field B, we investigated disease incidence among the fixed-point-survey plants and the surrounding 8 plants on the same dates as the Field A surveys. As in Field A, we also counted the number of total, diseased, and healthy panicles of the fixed-point-survey plants in Field B in early August. We judged plants to be diseased if they showed typical rice stripe disease symptoms, such as wilted new leaves, mottled leaves, or deformed panicles. We categorized diseased plants identified during the early July survey as "mid-June to early-July onset" plants, those newly identified during the early-August survey as "mid-July to early-August onset" plants, and those newly identified during the early September survey as "mid-August to early-September onset" plants. Because the area chosen for this study is almost entirely free of pests and diseases other than rice stripe

disease, we ignored the presence of other pests and diseases. In the same manner as in 2012, we investigated disease incidence on the fixed-point-survey plants in 2013 and 2014. Surveys were conducted on 11 and 12 July, 8 and 9 August, and 29 August 2013, and on 10 July, 7 and 8 August, and 28 August 2014.

2.3 Yield survey

In 2012, we harvested all fixed-point-survey plants that developed rice stripe disease up to harvest time, and evaluated the number of total, healthy, and diseased panicles, the brown rice yield, the number of brown rice kernels, and the 1000-kernel weight of each plant. We also randomly harvested half of the disease-free fixed-point-survey plants in each plot and evaluated yield in the same manner. In cases in which a fixed-point-survey plant was unlikely to yield a large enough sample for analysis, we also harvested surrounding plants. The above measurements were taken after harvesting individual plants from the survey fields and drying them naturally for a month inside field cages. In conformity with Japanese survey standards for paddy rice yield (Hosaka 2014), any brown rice grains with a diameter of ≤1.69 mm were excluded from the survey.

2.4 Statistical analysis

We conducted two-way ANOVA for brown rice yield, total number of panicles, the

number of healthy panicles, and 1000-kernel weight by survey field, disease onset period, and their interaction. When two-way ANOVA showed the disease onset period to have a significant effect, we performed the Tukey-Kramer HSD test as a post-hoc test. To analyze the relationship between the number of healthy panicles and brown rice yield, we conducted simple regression analysis of yield on the number of healthy panicles for each disease onset period. We used Pearson's correlation coefficient to analyze the relationship between the number of panicles at the flowering stage and at harvest, and conducted paired t-tests to confirm that the difference in the number between flowering and harvest was significant. To investigate how the disease spreads, we performed spatial autocorrelation analysis using join-count statistics (Cliff and Ord 1981, Plant 2012) on the data from the 30-row × 73-plants-per-row survey plot in Field A, in which all plants were checked for disease. We used the *spdep* package (Bivand et al. 2013) for version 3.3.3 of the R statistical software (R Core Team 2017) for the joincount statistical analyses, and version 12.2.0 of the JMP software (SAS Institute, Cary, NC, USA) for the other analyses.

3. Results

3.1 Change in disease incidence in survey fields

Figure 1 shows the change in disease incidence over time among the fixed-point-survey

plants in the two study fields from 2012 to 2014. In 2012, disease incidence in Field A increased remarkably, from 6.7% in the early-July survey (at the panicle initiation stage) to 57.3% in the early-August survey (at the flowering stage), to 68.0% by harvest time. Although Field B was less severely affected, disease incidence showed the same trend, rising rapidly from 2.0% in early July to 34.7% in early August and then gradually to 41.3% in early September (at harvest). In 2013 and 2014, the incidences of diseased plants in early July were higher than in 2012 (44.0%, 20.0%, 35.4%, and 52.0% in Fields C, D, E, and F, respectively), and the disease spread quickly throughout the test plot by early August (reaching 98.0%, 93.0%, 96.0%, and 96.0% in Fields C, D, E, and F, respectively). As a result, the percentages of diseased plants plateaued in late August (at 100%, 97.0%, 100%, and 97.0% in Fields C, D, E, and F, respectively). Most diseased plants showed typical rice stripe disease symptoms, with new leaves in the early-July survey drooping instead of fanning out, or showing mottle symptoms, and most of the diseased plants newly identified in the early-August and with early-September surveys showing deformed panicles.

3.2 Spatial autocorrelation among the plants that developed rice stripe disease

Of the 2181 plants (the total after excluding 9 missing plants) surveyed in Field A in

195 2012, 6.8% were symptomatic in the early-July survey, and 55.8% were symptomatic in

the early-August survey (Fig. 2). We conducted spatial autocorrelation tests using join-count statistics to analyze the relationships among the diseased plants found in early July (V), newly diseased plants found in early August (V2), and healthy plants found in early August (H). The number of joins for V and V, for V2 and V2, and for V and V2 were significantly higher than the expected values based on the assumption of a random distribution (Table 1). This means that the diseased plants identified in early July tended to be spatially congregated, and that diseased plants newly identified in early August tended to be distributed close to those identified in early July and to each other.

3.3 Damage to plants affected by rice stripe disease

We harvested both diseased and healthy plants from the fixed-point-survey plants in Fields A and B to analyze disease damage. Because we were unable to obtain sufficient diseased fixed-point-survey plants for analysis, we also harvested diseased plants around the survey plants. In total, we harvested 146 plants from Field A (including 127 fixed-point-survey plants) and 113 plants from Field B (including 93 fixed-point-survey plants). Table 2 shows the brown rice yield, number of brown rice kernels, brown rice 1000-kernel weight, number of panicles, and number of healthy panicles on these 259 plants for each disease-onset period and survey field.

3.3.1 Relationship between disease onset period and yield

- 215 The earlier a plant developed disease symptoms, the lower was its yield. Two-way
- 216 ANOVA showed that the disease onset period significantly affected brown rice yield (df
- = 3, SS = 5996.28, F = 27.53, P < 0.001), but that the survey field (df = 1, SS = 7.40, F
- = 0.10, P = 0.750) and its interaction with the disease onset period (df = 3, SS = 463.09,
- F = 2.13, P = 0.097) did not. Post-hoc Tukey–Kramer HSD tests showed that the brown
- 220 rice yield of the early-July onset plants was significantly lower than that of plants that
- developed symptoms later and of plants that remained healthy, and that the yield of
- 222 mid-July to early-August onset plants was higher than that of early-July onset plants but
- lower than that of healthy plants. No significant difference in brown rice yield was
- found between mid-August to early-September onset plants and plants that showed no
- symptoms (Fig. 3).
- 226 3.3.2 Relationship between disease onset period and 1000-kernel weight
- 227 Two-way ANOVA indicated that the survey field had a significant effect on the 1000-
- kernel weight (df = 1, SS = 6.89, F = 27.62, P < 0.001), but that the disease onset period
- (df = 3, SS = 0.02, F = 0.031, P = 0.993) and its interaction with the survey field (df =
- 230 3, SS = 0.86, F = 1.14, P = 0.332) did not.
- 231 3.3.3 Relationship between disease onset period and panicle numbers
- 232 Two-way ANOVA showed that the disease onset period had a significant effect on the
- total number of panicles (df = 3, SS = 653.14, F = 6.69, P < 0.001), whereas the survey

field (df = 1, SS = 36.99, F = 1.14, *P* = 0.288) and the interaction (df = 3, SS = 64.08, F = 0.66, *P* = 0.580) did not. The *post-hoc* Tukey–Kramer HSD test showed that the total number of panicles in the early-July onset plants was significantly lower than that of plants that developed symptoms at other times, and that there was no significant difference in the total number of panicles between mid-July to early-August onset plants, between mid-August to early-September onset plants, and between plants

Two-way ANOVA showed that the disease onset period had a significant effect on the number of healthy panicles (df = 3, SS = 3066.0, F = 27.17, P < 0.001), whereas the survey field (df = 1, SS = 2.38, F = 0.06, P = 0.802) and its interaction with the disease onset period (df = 3, SS = 108.28, F = 0.96, P = 0.413) did not. *Post-hoc* Tukey– Kramer HSD tests confirmed that the earlier a plant developed symptoms, the lower the number of healthy panicles it produced, and indicated that there was no significant difference in the number of healthy panicles between mid-August to early-September onset plants and plants that showed no symptoms (Fig. 4).

3.3.4 Relationship between the number of healthy panicles at harvest and brown rice

yield

showing no symptoms (Fig. 4).

Because the relationships between the disease onset period and brown rice yield or the number of healthy panicles were unaffected by the survey field, we combined data from both fields to conduct a simple regression of yield on the number of healthy panicles for

each disease onset period. This analysis confirmed that, regardless of the disease status or disease onset period, a greater number of healthy panicles at harvest time was associated with a greater brown rice yield (for mid-June to early-July onset plants: df = 1, SS = 5904.98, F = 757.47, P < 0.001; for mid-July to early-August onset plants: df = 1, SS = 6118.19, F = 512.35, P < 0.001; for mid-August to early-September onset plants: df = 1, SS = 1148.09, F = 136.75, P < 0.001; for plants with no symptoms: df = 1, df = 1,

3.4 Relationship between the number of panicles at flowering and at harvest

We used data for the 220 fixed-point-survey plants surveyed up to harvest (127 in Field A, 93 in Field B) to analyze the relationship between the number of panicles at flowering and at harvest: neither the total number of panicles nor the number of healthy panicles differed by survey field. Thus, we combined the data from both fields for this

analysis. Pearson's correlation coefficient for the relationship between the number of healthy panicles at flowering and at harvest was 0.920 (95% confidence interval [CI] = 0.897 to 0.938), that for the number of diseased panicles at flowering and at harvest was 0.889 (95% CI = 0.857 to 0.914), and that for the total number of panicles at flowering and at harvest was 0.870 (95% CI = 0.833 to 0.899), indicating strong and significant positive correlations between the number of panicles at flowering and at harvest for healthy, diseased, and total panicles (Fig. 6). The mean number of healthy panicles was 23.81 at flowering and 23.72 at harvest, versus 2.54 at flowering and 2.68 at harvest for diseased panicles and 26.35 at flowering and 26.40 at harvest for the total number of panicles. Paired *t*-tests showed that there was no significant difference between the mean number of panicles at flowering and at harvest for healthy panicles (df = 219, t = 0.47, P = 0.638), diseased panicles (df = 219, t = -1.36, P = 0.175), and total panicles (df = 219, t = -0.390, P = 0.697).

4. Discussion

In 2012, rice plants infected with rice stripe disease started to appear in mid-June to early July, after which the disease spread rapidly during the following month. In 2013 and 2014, the disease spread rapidly throughout the test plot by early August, and as a result, the percentages of diseased plants in early August were much higher than those

in 2012. The reason for the high incidence of the disease in 2013 and 2014 was likely the large number of first-generation adults of SBPH that migrated into the rice paddies in mid-June. Even under such conditions, the patterns of spread of the disease resembled that in 2012: diseased plants started to appear in mid-June to early July, and then the number increased during the following month. As paddy-colonizing firstgeneration SBPH adults appear in mid-June, second-generation nymphs appear in late June to early July, and third-generation nymphs appear in late July to early August in the study area, and as symptoms of rice stripe disease appear 10 to 15 days after a plant has been infected with RSV (Shinkai 1962), we conclude that the diseased plants observed in the early July were infected mainly by the first-generation SBPH adults, and that the subsequently identified diseased plants, which increased rapidly in number from mid-July to early August, were infected mainly by the second-generation nymphs and adults. The third generation contributed little to the increase of diseased plants because rice had entered its reproductive growth phase before these insects emerged in the field, when rice is less susceptible to RSV. Furthermore, spatial autocorrelation analysis using the detailed data from field A revealed that the mid-June to early-July onset plants tended to be distributed close to each other, and that the mid-July to early-August onset plants were congregated around the early-July onset plants. These observations suggest that rice stripe disease spreads within a paddy field through the following two-stage process: (i) first-generation adult SBPH carrying RSV colonize

paddy fields, where they infect rice plants as they move about and lay eggs; and (ii) second-generation nymphs and adults emerging within the paddy field infect plants adjacent to the previously infected plants. Most of the regions in Japan that are currently affected by rice stripe disease share many characteristics with our study site in terms of climate, cultivars, and cropping systems. Thus, the process by which rice stripe disease spreads and that was elucidated in this study should prove useful when pest control timing and methods are considered in other regions where this disease is prevalent. The magnitude of the damage caused by rice stripe disease differs greatly with the timing of disease onset: earlier onset results in significantly lower brown rice yield. Similarly, earlier onset leads to a greater reduction in the total number of panicles and the number of healthy panicles. The decreases in the number of healthy panicles and brown rice yield were particularly dramatic in plants that developed disease symptoms in mid-June to early July. Susceptibility to RSV in rice has been reported to vary widely with growth stage (Hibino 1996, Wang et al. 2008), and our results confirm these earlier results. Plants that develop the disease before panicle initiation not only suffer considerable decreases in yield, but also become the starting points of new infections. To reduce the damage caused by this disease, pesticide-based control must be used to target the first-generation adults that are responsible for disease onset during this period. The diseased plants that were newly identified in the early-August survey (i.e., that developed the disease after the panicle initiation stage) suffered much less damage in

terms of the number of healthy panicles and brown rice yield than plants that developed the disease before the panicle initiation stage. The panicle initiation stage represents a midpoint in the growth of rice plants between vegetative and reproductive growth. Our results suggest that disease onset has less impact on yield once plants have entered the reproductive phase, which confirms previous results. However, even if the damage per plant is slight, the overall damage may be considerable because plants that develop disease symptoms during the reproductive phase account for a significant proportion of the total number of diseased plants in a field. Accordingly, pest control aimed at reducing damage caused by this disease should also target the second-generation nymphs and adults that cause disease onset after the panicle initiation stage. Diseased plants that were newly identified in the early-September survey after the flowering stage suffered even less damage, and no significant difference from healthy plants was observed in terms of the total number of panicles, the number of healthy panicles, or the brown rice yield. In addition, few plants develop disease after the flowering stage. Thus, we conclude that instances of the disease that developed after the flowering stage have no major impact on total rice yield. Pest control that targets plants after the flowering stage would therefore not be cost-effective and appears to be unnecessary.

We analyzed the relationship between brown rice yield and the number of healthy panicles. Our analysis demonstrates that yield can be adequately explained solely in terms of the number of healthy panicles at harvest, regardless of the disease status or

onset period. Furthermore, the 1000-kernel weight remained fairly consistent regardless of the disease status or onset period. These results indicate that (i) a decrease in the number of rice kernels associated with a decrease in healthy panicles is the direct cause of decreased yield; (ii) damage caused by rice stripe disease can be estimated by evaluating the number of diseased panicles at harvest time; and (iii) measures to minimize the number of diseased panicles are vital to mitigating damage from the disease.

The numbers of healthy and diseased panicles, and the total number of panicles, changed very little from the flowering stage onward. Because rice does not produce new tillers after the tillering stage, it is reasonable to expect that the total number of panicles at flowering and at harvest will be the same. The numbers of healthy and diseased panicles also changed very little from the flowering stage onward. This is likely due to the rapid decline in susceptibility of rice to RSV after the panicle initiation stage. These results indicate that the total number of panicles and the numbers of healthy and diseased panicles at harvest can be predicted with a high degree of accuracy by conducting surveys at the flowering stage. This means that although the damage caused by rice stripe disease can be estimated by counting diseased panicles at the harvest stage, the same assessment could be carried out earlier, at the flowering stage.

Controlling rice stripe disease requires integrated pest management that combines pesticide-based control of insect vectors, planting of RSV-resistant cultivars, and paddy

field management designed to interrupt the infection cycle of the disease. RSV-resistant cultivars can be developed by means of marker-assisted selective breeding using the rice stripe disease resistance gene Stvb-i (Hayano-Saito et al. 1998, Sugiura et al. 2004). In terms of paddy field management, elimination of rice rations by plowing paddy fields after harvest and removal of grass from the banks of paddy fields have proven effective in curbing rice stripe disease (Shiba et al. 2016). Our results suggest that in addition to these measures, pesticide-based control that targets first-generation SBPH adults that colonize paddy fields and the second-generation nymphs and adults born in the paddy fields would also be effective in mitigating damage. Controlling the firstgeneration adult vectors can be done by applying pesticides to seedling trays when sowing the seeds or when transplanting the seedlings. This method can also be effective against the second-generation nymphs and adults. However, since the effectiveness of pesticides may be lost if pesticides with a short residual effect are used, it would be advisable to apply additional pesticide as needed. We are now conducting field demonstrations in various regions of Japan of integrated pest management based on the ideas revealed in this study.

Figure legends

- Fig. 1. Seasonal changes in the distribution of plants with rice stripe disease in the rice
 paddies. Each colored cell represents fixed-point-survey plants in each test plot. Rice
 plants were surveyed in early July (panicle initiation stage), early August (flowering
 stage), and late August or early September (full maturity). The numbers of surveyed
 plants were 148 in Field A, 150 in Field B, 100 in Field C, 100 in Field D, 99 in Field E,
 and 100 in Field F.
- Fig. 2. Detailed distribution of plants with rice stripe disease in the test plot of Field A in 2012. Each cell represents one plant.
 - **Fig. 3.** Effect of disease onset period on brown rice yield per plant (g). Boxes show the median, 25th, and 75th percentiles; \times shows the mean; ends of whiskers extend to the furthest point within the 1.5 interquartile range from the box; \circ outliers. Boxes marked with the same letter do not differ significantly (Tukey–Kramer HSD test, P < 0.05). The numbers of samples were 48 for mid-June to early-July onset plants, 127 for mid-July to early-August onset plants, 31 for mid-August to early September onset plants, and 53 for plants showing no symptoms.
 - **Fig. 4.** Effect of disease onset period on the total number of panicles and the number of healthy panicles. Boxes show the median, 25th, and 75th percentiles; × shows the mean; ends of whiskers extend to the furthest point within the 1.5 interquartile range from the box; outlier. Boxes marked with the same letters do not differ significantly (Tukey—

493	Kramer HSD test: $P < 0.05$; A, B: total; a, b, c: healthy). The numbers of samples were
494	48 for the mid-June to early-July onset plants, 127 for the mid-July to early-August
495	onset plants, 31 for the mid-August to early September onset plants, and 53 for plants
496	showing no symptoms.
497	Fig. 5. Relationship between the number of healthy panicles and brown rice yield (g) in
498	four rice stripe disease onset periods. The numbers of samples were 48 for the mid-June
499	to early-July onset plants, 127 for the mid-July to early-August onset plants, 31 for the
500	mid-August to early September onset plants, and 53 for plants showing no symptoms.
501	Fig. 6. Correlations (Pearson's r) between the number of panicles at flowering and at
502	harvest. The number of samples in each plot was 220.
